Abstract

Polychelidan lobsters, as the sister group of Eupreptantia (other lobsters and crabs), have a key-position within decapod crustaceans. Their evolutionary history is still poorly understood, although it has been proposed that their Mesozoic representatives largely inhabited shallow-marine environment and only later sought refuge in deep water. This view has recently been challenged, so the evolutionary history of polychelidans is in a need of re-appraisal. The earliest representatives, such as *Tetrachela* from the Late Triassic of Austria and Italy, are of great importance because of their potential in investigation of life habits of early polychelidans. *Tetrachela* lived in a relatively deep water, however, its well-developed eyes suggest an environment where light was still present. With its massive dorsoventrally flattened body plan, *Tetrachela* was probably benthic; the shape of its mandible and stocky first pereopods suggest it was a scavenger and/or fed on slowly moving or sedentary animals. The carapace of *Tetrachela* has a peculiar groove pattern, which leads us to redefine some elements of the nomenclature of grooves used for polychelidans. Based on the present revision we propose that the second incision and its associated groove correspond to the hepatic groove, not the postcervical or the branchiocardiac grooves as interpreted previously. This revision allows us to review the homologies of cephalothoracic groove between polychelidans and other notable groups of decapod crustaceans.

Introduction

Polychelidan lobsters can be considered as the coelacanth of decapod crustaceans: fossil species were the first to be discovered (Desmarest, 1817), were morphologically diverse, and lived in various palaeoenvironments (Audo *et al.*, 2014a, c; Bravi *et al.*, 2014; Jauvion *et al.*, 2016); extant species, on the contrary, were discovered later (Heller, 1863), are morphologically less diverse, and restricted to deep-water environments (Galil, 2000; Ah Yong, 2009). This peculiar distribution was tentatively explained by Beurlen (1931), who postulated that polychelidans first inhabited shallow waters and later sought refuge in deep waters. This view was followed by Glaessner (1969) and refined by Ah Yong (2009). However, this model was recently criticized by Audo *et al.* (2014b, in press). More importantly, polychelidan lobsters have played a key role in decapod phylogeny, because Polychelida is considered to be the sister taxon to eupreptantians (Scholtz and Richter, 1995; Ah Yong and O'Meally, 2004; Bracken-Grissom, *et al.* 2014).

For these reasons, it is important to have a better understanding of the evolutionary history of polychelidan lobsters, including the significance of their earliest fossil occurrences. Indeed, these early species might give us

insights into the original life habits of polychelidans and also yield important morphological characters for the phylogenetic study not only of polychelidans but also decapod crustaceans. Polychelidan earliest occurrences date back to the Late Triassic (Carnian). Two species are known from that time interval; *Coleia uzume* Karasawa, Takahashi, Doi and Ishida, 2003, has been described from Japan (Karasawa *et al.*, 2003), and *Tetrachela raiblana* (Bronn, 1858) from the Alps on both sides of the current boundary between Italy and Austria. Both species are insufficiently known, partly because of the preservation of the available material. *Tetrachela raiblana* has so far not been adequately documented, probably because most specimens are incompletely preserved, often without the carapace, which presents numerous characters useful in systematic palaeontology. In this respect, detailed documentation of available carapaces presented herein fills the gap in the knowledge. As shown further below, the carapace in *T. raiblana* is especially interesting because it possesses a peculiar groove pattern (Beurlen and Glaessner, 1930: fig. 11) that at a first glance is different from that of other polychelidans (the groove pattern on *C. uzume* is indistinct due to the preservation). The significance of *T. raiblana* was recognized by Ahyong (2009), who used that species as the outgroup (or reference point) of his phylogenetic analysis of polychelidan lobsters.

The present contribution reviews *T. raiblana* and assesses its significance based upon the available material, including the only known surviving syntype and some especially well-preserved specimens. This revision leads to a better understanding of the homologies of cephalothoracic grooves between polychelidans and other decapods. We also propose an updated nomenclature for grooves based upon our interpretations. Finally, we briefly discuss the palaeoenvironment and palaeoecology of *T. raiblana*.

Geological settings

The sediments of the Raibl (Cave del Predil) and Polzberg lagerstätten were deposited during the Carnian (Late Triassic). At that time, the Alpine zone was located at the western extremity of the Neotethys Ocean, and both localities were located on the margin of the Hallstatt-Meliata Ocean, a small branch of the Neotethys (Hornung *et al.*, 2007).

Sediments exposed at both localities are approximately coeval and were deposited during what is known as the Carnian Pluvial Event (Hornung *et al.*, 2007), a biological crisis linked to a sudden climatic

perturbation which led to the demise of rimmed carbonate platforms (Keim *et al.*, 2001) and a switch to carbonate or mixed ramps (Bosellini *et al.*, 2003).

Raibl Beds (Cave del Predil). The Raibl Beds were discovered due to the nearby mining for lead, iron, and zinc that probably started in the Roman period (Boué, 1835; Nuova Raibl Soc. coop., 2016). The Lagerstätte of Raibl is represented by oil shales (bituminösen Schiefer: Bronn, 1858; see also Boué, 1835) also referred to as fish beds (Suess and Mojsisovics, 1867), which were probably deposited in deep water in a basinal environment (Rettori *et al.*, 1998; de Zanch *et al.*, 2000). This Lagerstätte has yielded fragments of plants and several species of fishes first mentioned by Boué (1835) and later described by Bronn (1858). It also has yielded several decapod crustaceans, including *Tetrachela raiblana*, *Antrimpos crassipes* (Bronn, 1858) and *Bombur aonis* Bronn, 1858. Among fishes, one species, *Thoracopterus niederristi* Bronn, 1858 also occurs at the Polzberg locality (Griffith, 1977).

Polzberg Lagerstätte. The Reingraben shales are exposed at the Polzberg Lagerstätte. This Lagerstätte has regularly been associated and described with the nearby Lunz Lagerstätte, although these two differ in age, environment, and taphonomic pathways (Forchielli and Pervesler, 2013). The Polzberg Lagerstätte (*sensu* Forchielli and Pervesier, 2013) is characterized by its low energy setting (no bottom currents), occasional low-oxygen levels indicated by accumulations of the juvenile bivalves *Halobia* (McRoberts, 2001; Hopkin and McRoberts, 2005). The Polzberg Lagerstätte has yielded a diverse fauna of fishes (Griffith, 1977), ammonites (Glaessner, 1931), and a rich fauna of arthropods. Decapod crustaceans include *Antrimpos straeleni* (Glaessner, 1929), *Antrimpos crassipes* (also known from Cave del Predil), *Clytiella spinifera* Glaessner, 1931, *Platychela trauthi* Glaessner, 1931 and *T. raiblana*. In addition, two species of thylacocephalans also occur there (Glaessner, 1931).

Material and methods

This study is based upon 43 specimens. These specimens appear dark, almost black, sometimes with patches of white, on a dark grey limestone. Specimens are generally visible in ventral view, almost complete, but missing the carapace.

Specimens from the Museo Friulano di Storia Naturale (MFSNgp, Udine, Italy) and from the

Museo Paleontologico Cittadino della Rocca di Monfalcone (MPCM, Monfalcone, Italy) were documented under cross-polarized light to enhance the contrast between the matrix and the specimen by avoiding direct reflections on the surface of the sample (Bengtson, 2000). Specimens from Harvard Museum of Comparative Zoology (MCZ, Cambridge, Massachusetts, United States of America) and Natural History Museum (NHMUK, London, United Kingdom) were photographed in natural light, in some cases, soaked in alcohol, for the NHMUK specimens. The specimens from the Geologische Bundesanstalt (GBA, Vienna, Austria) were documented in natural light and whitened by an ammonium chloride coating.

In order to compare the morphology of *T. raiblana* to other groups of decapod crustaceans, we also examined four specimens of extant decapod crustaceans from the zoology collections of Muséum national d'Histoire naturelle (MNHN-IU, Paris, France). Three of these specimens were collected during oceanic cruise expeditions led by the Institut de Recherche pour le Développement (IRD) and the Muséum national d'Histoire naturelle (MNHN) (Bouchet *et al.*, 2008). These specimens were photographed under polarized white light.

Type genus: *Tetrachela* Reuss, 1858

Included genera: Monotypic subfamily

Occurrence: Late Triassic (Italy, Austria).

Original diagnosis by Beurlen (1930: 339). „Karapax gerundet rechteckig, mäßig stark verbreitert. Regionengliederung stark differenziert. Augen

wohl entwickelt, nach vorn gerichtet, in schwachen Ausschnitten des Vorderrandes, seitlich des breiten Stirnrandes. Antennengeißeln kurz. Dritter Maxillarfuß mit verbreiterem Ischium. Telson breit gerundet; Diäresis vorhanden.“

Literal translation in modern terms. Carapace with a rounded rectangle outline, moderately widened. [Carapace] with distinct regions. Eyes well-developed, facing forward, in shallow incisions on the anterior margin, on the side of the wide frontal margin. Short antennae. Third maxilliped with a wide ischium. Telson broad and rounded. Diaeresis present.

Emended diagnosis by Pinna (1968: 102). “Cefalotorace fortemente allargato, subrettangolare. Margine anteriore largo e diritto con incisioni oculari laterali ed occhi ben sviluppati rivolti in avanti. Due incisioni laterali poco profonde. Carene assenti. Telson arrotondato e largo. Dieresi presente.”

Literal translation in modern terms. Cephalothorax very wide, subrectangular. Frontal margin wide and straight with lateral ocular incisions with well-developed eyes facing forward. Two shallow lateral incisions. Carina lacking. Telson rounded and wide. Diaeresis present.

Emended diagnosis by Glaessner (1969: R468). “Carapace almost quadrangular, with orbital emarginations, granulate, cervical and branchiocardiac grooves strongly marked, V-shaped, postcervical groove connected with both; telson rounded, uropods with diaeresis.”

Emended diagnosis by Ahyong (2009: 381). “Carapace with shallow orbits located on anterior margin; eyes well-developed, apparently directed anteriorly; without median carina anterior to cervical groove; cervical and branchiocardiac grooves distinct across carapace, not meeting, indicated at lateral margins by notches. Abdominal pleuron 2 similar to pleuron 3, not overlapping pleuron 1. Uropodal exopod with straight diaeresis. Telson rounded distally. Pereopod 1 dactylus tapering distally, longer than pollex. (Based on Glaessner 1969.)”

Emended diagnosis by Karasawa et al. (2013: 98). “Carapace almost quadrangular with orbital emarginations, dorsoventrally flattened, rostrum indistinct; antennal groove absent; cervical and branchiocardiac grooves strongly marked and V-shaped, extending to median; postcervical groove connected with cervical and branchiocardiac grooves; branchial and thoracic median carinae present; epistome and carapace not in broad contact. Pleon with axial keel and sharp demarcation between terga and

pleura; telson subrectangular; exopod of uropods with diaeresis. Antennular stylocerite present; maxilliped 3 dactylus sharp; pereopods 1-4 chelate; pereopod 5 unknown.”

Emended diagnosis (present work). Dorsoventrally flattened carapace subrectangular in outline in dorsal view; concave frontal margin placed more anteriorly than outer angle of ocular incision; deep U-shaped ocular incision, laterally enclosed by lateral margin, opening anteriorly; marked cervical and hepatic incisions; cervical incision deeper than hepatic incision; posterolateral angle extending slightly along s1; cervical groove cutting median line deeply; large gap between anterior and posterior part of branchial carina; posterior part of branchial carina rather short; hepatic groove distinctly merged with branchiocardiac groove, not intersected by branchial carina; telson well-rounded; third maxilliped ischium roughly kidney-shaped; first pereopod distinctly larger than the others and rather stocky; pereopod 5 ending in a small chela, at least in some individuals (possibly variable due to sexual dimorphism); uropodal exopod with a diaeresis forming an arc of circle.

Remarks. Tetrachelinae are assigned to Polychelida based upon their dorsoventrally flattened carapace (shield), their concave frontal margin, their pattern of cephalothoracic grooves and carina, and of their chelate pereopods 1-4. More precisely, Tetrachelinae are placed within the diverse Coleiidae by their marked cervical and hepatic incisions, with cervical incision deeper than hepatic; the cervical groove curved medially near median line, and the presence of a diaeresis. The scaphocerite of Tetrachelinae appears to be rounded with a median carina, a character typical of Coleiidae. However, the preservation of the scaphocerite is rare and the few preserved ones are poorly preserved and therefore difficult to interpret. We note that in Ahyong (2009), *Tetrachela* was not placed “near *Coleia*” in his cladogram. It is important to observe that Ahyong (2009) used *Tetrachela* as the outgroup of his analysis. This implies that the position of *Tetrachela* in this cladogram was fixed at the base of the cladogram, by definition. Consequently, we cannot judge if Ahyong (2009) results are compatible or not with our suggestion that Tetrachelinae belongs to Coleiidae. In the analysis of Karasawa et al. (2013), *Tetrachela* is resolved as sister-group to *Coleia* Broderip (1835) and *Polychelès* Heller (1862). Karasawa et al. (2013) proposed closer relationships between Coleiidae and Polychelidae, which differs from our suggestion to include Tetrachelinae within

Coleiidae. Such a discrepancy is considered to represent an effect of limited sampling of Coleiidae in Karasawa et al. (2013). Indeed, Karasawa et al. (2013) focuses upon the relationships of all fossil lobsters rather than on those within polychelidans. More detailed phylogenetic analysis using also an outgroup outside Polychelida and a more extensive sampling of Coleiidae (still under development) will be required to assess the affinities of *Tetrachela*.

Type species: *Bolina raibлана* Bronn, 1858, by monotypy.

Included species: monospecific genus.

Distribution. Carnian (Italy, Austria).

Diagnosis by Zittel (1885: 686). „Cephalothorax nie erhalten, ursprünglich sehr dünn, mässig breit, ebenso lang als das Abdomen. Hinterstes Kiemenfusspaar kräftig entwickelt, aber kurz. Die 4 vorderen Fusspaare des Thorax mit Scheeren; die Scheere des ersten mit einer grossen Hand und einem beweglichen Index. Telson hinten gerundet; die beiden Blätter des hintersten Schwimmfusses breit.“

Literal translation in modern terms. Cephalothorax never preserved, initially very thin, moderately wide, as long as the pleon. The last pair of pleopods well-developed, but short. The anterior four pairs of pereopods chelate. First chela with a large palm and a movable index. Telson rounded, uropodal exopod and endopod broad.

Remarks. *Tetrachela* being the type and only genus of Tetrachelinae, its diagnosis is identical to that of the subfamily. See the present emended diagnosis.

Type material. Lectotype herein designated: without collection number “Originaliensammlung” collection, Institute of Geosciences, University of Heidelberg (Figure 1 – examined).

Type locality. Cave del Predil (also known as “Raibl”), Friuli-Venezia Giulia, Italy (Bronn, 1858, Roghi, 2004).

Type age. Carnian.

Occurrence. *Tetrachela raiblana* has so far been reported only from thin shales of Cave del Predil (Italy) and the Polzberg Lagerstätte (Austria).

Additional material. 43 specimens: GBA 1858/004/0002/01, 1858/004/0002/02, 1930/002/0002/01 (Figure 2A). — NHMUK 41870 (Figure 3A), 41876, 44953, I.3256 (6 samples), one additional specimen without collection number. — MCZ6252/1, MCZ6252/2, MCZ6252/3. — MFSNgp 01191, 15538 (Figure 2C), 15539–15540, 15594, 15598, 16884, 19249, 19583 (Figure 2B), 19587, 19591, 21032, 22860, 33976. — MPCM 2508–2509 (part and counterpart; Figure 3B), 2512, 2514, 2517, 3541, 3543–3544, 4839, 4866, 7701. — SNSB-BSPG 1969 XII 2, 1969 XII 3.

Description. Outlines of carapace (cephalothoracic shield) (Figure 4R). — Dorsoventrally flattened carapace, subrectangular in outline in dorsal view; concave frontal margin (poorly preserved), placed slightly more anteriorly than the outer angle of ocular incision; anterolateral angle probably produced into a short spine (poorly preserved); lateral margin smooth, cut by ocular, cervical and hepatic incisions; deep U-shaped ocular incision, laterally enclosed by the lateral margin, opening anteriorly; anterolateral

margin slightly convex, very slightly oblique; cervical and hepatic incisions opening in the anterior half of the lateral margin; deep subtriangular cervical incision; straight mediolateral margin, shorter than anterolateral margin; hepatic incision shallower than cervical incision; rounded posterolateral angle, extending slightly along pleonite 1, contiguous to pleonite 1 lateral margin; concave posterior margin, wider than frontal margin.

Grooves and carinae of carapace (Figure 4R). Postrostral and postcervical carinae separated by cervical groove; postrostral carina short, limited to the posterior half or third between frontal margin and cervical groove; postcervical carina extending from cervical groove to posterior margin, cutting postcervical groove; short and raised anterior part of branchial carina (= postorbital carina?) curving inward anteriorly; posterior part of branchial carina rather short, separated from the anterior part by a large gap, marked from the branchiocardiac groove to the posterior margin; deep cervical groove marked across carapace, curving slightly near median line, cutting deeply median line; deep postcervical groove, almost joining hepatic-branchiocardiac grooves at their junction point, forming a transverse arc, joining median line without cutting it; deep intercervical groove extending from cervical groove toward postcervical groove, not merging with postcervical groove; deep hepatic groove extending from the hepatic incision (ventral side not preserved), and joining with branchiocardiac groove; branchiocardiac groove forming a right angle with hepatic groove, extending posteriorly toward the branchial carina, then oblique from the branchial carina toward median line, not reaching median line.

Pleon and telson. Pleon about as long as carapace, and slightly narrower than carapace; pleonite 1 shorter than others (poorly preserved); dorsal portion of terga (excluding tergopleura) of pleonites 2–5 with a pair of transverse groove converging medially and a slightly raised axial carina cutting posterior transverse groove; tergopleura of pleonites 2–5 apparently lanceolate (poorly preserved); dorsal portion of terga (excluding tergopleura) of pleonite 6 subtrapezoidal; tergopleura of pleonite 6 subtriangular and narrow; telson well-rounded distally.

Eye and cephalic appendages. Eye entirely contained in the ocular incision; antennula with two flagella carried by a short peduncle (poorly preserved); antenna with a short flagellum (poorly preserved); mandible composed of a large subtriangular protopodite carrying an incisive process with large

Figure 4. Comparison of the general outline of carapaces, revised (right sides omitted, adapted from Audo *et al.* in press and Audo *et al.* 2017) of the type species of each genus of fossil Polychelida: **A**, *Adamanteryon fourneti* Audo, Schweigert, Saint Martin and Charbonnier, 2014; **B**, *Antarcticheles antarcticus* Aguirre-Urreta, Buatois, Chernoglasov and Medina, 1990; **C**, *Coleia antiqua* Broderip, 1835; **D**, *Cycleryon propinquus* (Schlotheim, 1822); **E**, *Eryon cuvieri* Desmarest, 1817; **F**, *Gabaleryon coquelae* Audo, Williams, Charbonnier and Schweigert, 2017.; **G**, *Hellerocaris falloti* (Van Straelen, 1923); **H**, *Knebelia bilobata* (Münster, 1839); **I**, *Palaeopentacheles roettenbacheri* (Münster, 1839); **J**, *Palaeopolycheles longipes* (Fraas, 1855); **K**, *Proeryon hartmanni* (Meyer, 1836); **L**, *Pseudocoleia mazzolenii* Garassino and Teruzzi, 1993; **M**, *Rogeryon oppeli* (Woodward, 1866); **N**, *Rosenfeldia triasica* Garassino, Teruzzi and Dalla Vecchia, 1996; **O**, *Soleryon amicalis* Audo, Charbonnier, Schweigert and Saint Martin, 2014; **P**, *Tauricheles crymensis* (Levitski, 1974); **Q**, *Tethyseryon campanicus* Bravi, Garassino, Bartiromo, Audo, Charbonnier, Schweigert, Thévenard and Longobardi, 2014; **R**, *Tetrachela raiblana* (Bronn, 1858); **S**, *Tonneleryon schweigerti* Audo, 2016; **T**, *Tropifer laevis* Gould, 1857; **U**, *Voulteryon parvulus* Audo, Schweigert, Saint Martin and Charbonnier, 2014; **V**, *Willemoesiocaris ovalis* (Van Straelen, 1923); **W**, *Woodwardicheles neocomiensis* (Woodward, 1881); **X**, *Wrangelleryon perates* Feldmann, Schweitzer and Haggart, 2013. Illustrations not to scale.

median teeth framed by smaller anterior and posterior teeth.

Thoracic appendages (outline in ventral view). Third maxilliped (thoracopod 3) with an ischium roughly kidney-shaped and stocky distal podomeres; large chelate pereiopod 1 (P1: thoracopod 4); subtriangular P1 basis; stocky ischium with slightly rounded anterior and posterior margins; subrectangular P1 merus, longer than ischium; subtriangular, slightly rounded P1 carpus; stocky P1 propodus palm; straight P1 pollex with a slightly curved distal part; straight dactyl with a curved distal part; pereiopods 2 to 4 (P2–P4: thoracopods 5–7) chelate, of decreasing size from P2 to P4; pereiopod 5 (thoracopod 8) ending in a small chela (only visible in two specimens, not preserved or unclear for others).

Pleonal appendages. Pleopods poorly preserved; uropod with short basipod carrying a rounded endopod strengthened by a median carina and a rounded exopod which posterolateral border is cut by the diaeresis forming an arc of circle.

Ornamentation. Dorsal surface densely covered by tubercles; smooth pereiopods, except for the outer margin of P1 propodus, which is covered by small tubercles.

Remarks. The description of *Bolina raiblana* Bronn, 1858 is based upon seven syntypes. Only one of these syntypes (Bronn, 1858 pl. 4, fig. 3) has been rediscovered in the “Originaliensammlung” collection housed in the Institute of Geosciences, University of Heidelberg. Other syntypes appear to have been lost or misplaced for a long time because they were not mentioned in the literature. Part of Bronn’s collection is now in Harvard Museum of Comparative Zoology (MCZ) collections and does include specimens of *Tetrachela*, but they do not match individuals presented in Bronn (1858). Our search or inquiries at Geologischen Bundesanstalt (Vienna, Austria) or in the various collections, which might have housed the rest of this historic material, were not successful. Since Bronn (1858) illustrated only three of the seven syntypes, and because other crustacean species occur in the same outcrop, we designate the specimen herein illustrated in Figure 1 as the lectotype of *Tetrachela raiblana* (Bronn, 1858). This lectotype designation should limit future instability of nomenclature.

Reuss (1858) described *Stenochelus triasicus* based upon a single specimen from the same locality as *Tetrachela raiblana*. This specimen, which was not located and might also be lost, is known from a good illustration (Reuss, 1858: pl. 1, fig. 1). Oppel

(1862) considered *S. triasicus* as synonymous with *T. raiblana*. This opinion was followed by Glaessner (1929a, 1930). Detailed observation of the illustration in Reuss (1858) lead us to agree with this synonymy. Indeed, the general outline of carapace and the shape and position of carinae and grooves are identical to that documented for *T. raiblana*.

Discussion

Nomenclature of grooves

The first reconstruction of *Tetrachela raiblana* was provided by Glaessner (1929b: pl. 9, fig. 1). This reconstruction was refigured several times (Beurlen and Glaessner, 1930; Glaessner, 1969; Ah Yong, 2009; Karasawa *et al.*, 2013) without further examination, and was used as a basis for the phylogenetic analysis of Ah Yong (2009) and possibly Karasawa *et al.* (2013). Based upon this reconstruction, *T. raiblana* appears to have a cephalothoracic groove pattern very different from that of other fossil and extant polychelidans, with several additional grooves. However, our reinvestigation reveals that this reconstruction was partially incorrect. Indeed, it seems these authors drew the branchiocardiac groove completely straight, instead of sinuous, and misinterpreted some fractures of the carapace for additional grooves.

From our observations, the grooves of *T. raiblana* are rather similar to that of other polychelidans (Figure 4). However, due to a larger gap between the anterior and posterior part of branchial carina, grooves are more marked, and their relations lead us to reconsider their nomenclature. Indeed, the transverse groove connected to the posterior incision is clearly linked to the branchiocardiac groove. Therefore, it suggests that the part of the groove extending from that posterior incision could be referred to as “branchiocardiac groove”, and the corresponding incision as “branchiocardiac incision” (as proposed by Van Straelen, 1925; Glaessner 1969; Karasawa *et al.*, 2013; and Feldmann *et al.*, 2013b). It should not be referred as “postcervical groove” (contrary what is proposed by Galil, 2000; Ah Yong and Brown, 2002; Ah Yong and Galil, 2006; Ah Yong and Chan 2004, 2008; Ah Yong, 2009; Chang *et al.*, 2013; Artuz *et al.*, 2014; Audo *et al.*, 2014a; 2014b; 2014c; Bravi *et al.*, 2014; Jauvion *et al.*, 2016; Audo, 2016; Audo *et al.*, 2017). However, it could also be the “hepatic groove”, since it is the prolongation of this particular groove, which extend

from the junction of the antennal and cervical grooves and merges with branchiocardiac grooves in numerous crustaceans, such as glypheidans (Charbonnier *et al.*, 2013: fig. 9; Figure 5C) and several groups of clawed lobsters (Tshudy and Babcock, 1997: their fig. 2; see also Figure 5D). Although this solution has not been proposed yet, it has a practical application, indeed, in Polychelidae, the groove emerging from the posterior incision on lateral margin is clearly disconnected from

the branchiocardiac groove. We therefore propose to consider this groove as the dorsal portion of the hepatic groove, and the associated incision should be referred to as “hepatic incision”. We note that this proposition contradicts the nomenclature *sensu* Glaessner (1960: 39), who considered the hepatic groove to be a part of the branchiocardiac groove. From our perspective, it is useful to distinguish both grooves, as they are not always linked.

Figure 5. Homologies of carapace (shield) grooves in polychelidan lobsters and other reptantian crustaceans. **A**, *Hellerocaris falloti* (Van Straelen, 1923), MNHN.F.A47495, from the Callovian of La Voulte-sur-Rhône (France), lateral left view. **B**, *Stereomastis surda* (Galil, 2000), MNHN.IU.2016.10672, female, from Big Bay (Vanuatu), trawled at about 700 metres (BOA 1 oceanographic expedition), lateral left view. **C**, Sketch of a glypheid lobster; **D**, *Nephrops norvegicus* (Linnaeus, 1758), MNHN.IU – unknown number, lateral left view. **E–G**, *Ibacus alticrenatus* Bate, 1888, MNHN.IU.2017.10263, male, from Bligh Water (Fiji Islands), trawled at about 380 m (MUSORSTOM 10 oceanographic expedition), dorsal view (E–F) and ventro-lateral view (G); **H**, *Scyllarides squamosus* (H. Milne Edwards, 1837), MNHN.IU.10262, male, origin unknown, lateral right view. Abbreviations: **a**, branchiocardiac groove; **b**, antennal groove; **b₁**, hepatic groove; **c**, postcervical groove; **cd**, cardiac groove; **cd?**, possibly homologous with cardiac groove; **d**, gastro-orbital groove; **e₁e**, cervical groove; **i**, inferior groove; **ic**, intercervical groove; **ic?**, possibly homologous with intercervical groove. Scales: 10 mm (A–B), 20 mm (D–F). Images: Philippe Loubry (A), Denis Audo (B, D–H) and Charlène Letenneur (C).

Comparison with other Carnian polychelidans

Coleia uzume is known from only five rather poorly preserved specimens from the early Carnian of Japan (Karasawa *et al.*, 2003). Thus it is one of the oldest polychelidan species. Moreover it has been reported outside of Europe, where most fossil polychelidans have been discovered so far. For these reasons, it would be interesting to compare it to *T. raiblana*. Unfortunately, due to the preservation of the specimens, little can be used from the figures presented by Karasawa *et al.* (2003). The main difference between *C. uzume* and other polychelidans (including *T. raiblana*) appears to be the “inner branchial carina” which, however, most likely represents the posterior part of the ventral margin of the carapace superimposed to the dorsal carapace surface (the holotype and paratype of *C. uzume* are preserved in ventral aspect: Karasawa *et al.*, 2003, figs 2.1, 2.2).

Homologies of grooves between polychelidans and some other decapods

The grooves on the surface of the carapace of many crustaceans are linked with internal structures, such as muscles and epimerite (Glaessner, 1960; Secrétan, 1964). The pattern formed by these grooves presents important similarities between groups (Figure 5), for instance, the longitudinal antennal and hepatic grooves, transverse cervical and postcervical grooves are extremely common in decapods. However, identifying the homologies between grooves is not easy.

In the case of polychelidans, the carapace grooves are present on the ventral and dorsal surfaces of the carapace. The homologies of these grooves with other decapod crustaceans may be hypothesized from their connections.

(1) The most anterior groove, only visible ventrally, connects the anterior margin to the cervical incision (Audo *et al.*, 2014a, 2014c; Figures 4, 5A, 5B); from its position, it can only correspond to the antennal groove “b” occurring in many decapod crustaceans (Figure 5C, 5D, G–H; Boas, 1880; Van Straelen, 1925; Tshudy and Babcock, 1997; Tshudy and Sorhannus, 2003; Charbonnier *et al.*, 2013), with a notable exception of brachyurans.

(2) The transverse groove arising from the antennal groove and passing through the first incision (not counting ocular incision) is considered to correspond to the cervical groove; its homology with the cervical groove “e₁e” of other decapods can be established from its connection with antennal groove and gastro-orbital

groove (Figure 5); it should not be confused with the transverse groove cutting median line and resembling a cervical groove in astacids and nephropids (the postcervical groove, although it is mistakenly referred to as “e₁e” by Van Straelen, 1925: figs 25–27 and Chan and Yu, 1991: 21, who remarked that the terminology is particularly confusing for the two transverse grooves on the carapace), this latter groove corresponds to the second transverse groove, that is part of the hepatic, branchiocardiac, and even postcervical grooves in polychelidans.

(3) A groove is often visible between the branchial carina and median line, where the cervical groove is inflexed, extending anteriorly and slightly toward median line; from the connection of this groove, it seems most likely to represent a gastro-orbital groove “d”, homologous to that found in many other decapods (Van Straelen, 1925; Tshudy and Sorhannus, 2003; Charbonnier *et al.*, 2013; see Figure 5 – note that Van Straelen, 1925 in fig. 20 misinterpreted the anterior portion of the branchial carina as a gastro-orbital groove).

(4) On the ventral surface, the hepatic groove “b₁” is aligned with the antennal groove, curving to pass through the hepatic incision, and stretch transversally to join the branchiocardiac groove in *Tetrachela raiblana*; this groove was discussed in detail in the previous section, its homology with the hepatic groove is supported by the connection with other grooves (Figure 4R) and its position; however, its boundaries and connections with the branchiocardiac and postcervical grooves are more difficult to assess and vary depending on authors and the group they discuss (more on this matter below). We note that this groove is not visible ventrally in the scyllarids illustrated herein (Figures 5G–H).

(5) On the dorsal surface, just posterior to the cervical groove, a groove lies between branchial carinae. This groove seems almost connected to hepatic and branchiocardiac groove in most species of polychelidans; from its position and connection (Figure 4), it seems homologous to the postcervical groove “c” of other decapods such as nephropids (Figure 5D) and astacids (Tshudy and Babcock, 1997; Tshudy and Sorhannus, 2000) or glypheideans (Charbonnier *et al.*, 2013; Figure 5C); we note that the postcervical groove of polychelidans in most species is curved anteriorly near median line, in eryonids, rare species of polychelids and *Willemoesiocaris ovalis* (Van Straelen, 1923), the groove is more straight and parallel to the branchiocardiac groove; it is possible

that the curvature of this groove is in fact homologous to the cardiac groove “cd” of glypheidans (Charbonnier *et al.*, 2013; see Figure 5C).

(6) In *Tetrachela raiblana*, a short groove connected to the cervical groove extends toward postcervical groove, it could be considered as the intercervical groove “ic” (Figure 4R). A similar groove may also occurs in *Gabaleryon* Audo, Williams, Charbonnier and Schweigert, 2017 (Figure 4F).

(7) The most posterior groove that arises from the hepatic groove, running almost parallel to the branchial carina before curving toward the median line is the branchiocardiac groove “a”, since it is the last groove which delimits the branchial chamber, and consequently, no further groove can occur more posteriorly and laterally (Glaessner, 1960; see Figure 5).

(8) A small groove arising from the hepatic groove and extending ventrally is the inferior groove; it occurs in *Soleryon amicalis* (see Audo *et al.*, 2014a) and *Hellerocaris falloti* (see Figure 5A), but not *Stereomastis surda* (Galil, 2000) (see Figure 5B).

In polychelidans and glypheidans, the distinction between hepatic, postcervical and branchiocardiac grooves are rather obvious. On the contrary, for some astacids, and nephropids (Figure 5D), the hepatic groove is merged with a deep groove that cuts the median line deeply, posterior to this groove (see Tshudy and Sorhannus, 2003: fig. 2). In these species, it is more difficult to judge where the postcervical joins the hepatic groove and where the branchiocardiac groove begins. From what is visible in allied species (see Tshudy and Babcock, 1997; Tshudy and Sorhannus, 2000), it seems that the hepatic groove extends rather high on the carapace before merging with the branchiocardiac and postcervical grooves. This situation is, in summary, similar to that described in polychelidans. For scyllarids, the general disposition of grooves between branchial carina is similar to that of glypheidans, polychelidans and nephropids (Fig. 5E-H). However, from the branchial carina to the lateral margin and on the ventral side of carapace, the groove pattern is rather different. For this reason, the homologies of grooves are far from clear. Figure 5 E-F proposes two alternative views on the homology of grooves between scyllarids and other decapods. A detailed study of scyllarids and other achelates is required to test our proposals, however, such a study is outside the scope of the present research. Despite this uncertainty of homologies, it is clear that scyllarids differ substantially from polychelidans by the groove

pattern and/or carapace. This difference might be partially linked to the convergent flattening of the carapace in scyllarids and polychelidans, a process similar to “carcinization” (Scholtz, 2014).

Taphonomy

The absence of the carapace in most specimens of *Tetrachela raiblana* could imply they correspond to exuviae. Indeed, as discussed in detail by Audo (2016), polychelidan lobsters emerge from their old exoskeleton by rupturing the carapace along the median line and flipping it forward, which separates the carapace from the pleon. Despite the fact that most or all specimens of *T. raiblana* might correspond to exuviae, they still have their appendages and pleon associated (pleon is not visible in two specimens, for which the corresponding area is not prepared: MPCM 3544, NHMUK.3256). This association is interesting, because it was shown that the articulation between the anterior part of the exoskeleton and pleon is among the first to rupture in corpses (Allison, 1986, 1988; Plotnick, 1986). For exuvia and potential corpses (specimens which appear to be complete could correspond to corpses), we can postulate that finding the appendages and pleon closely associated implies that there was a limited transport and probably a rapid burial of these remains. These observations suggest that the studied individuals fossilised in the palaeoenvironment they inhabited (autochthonous) or were transported over only a short distance before final burial (paraautochthonous).

Palaeoenvironment

The sediments forming the Carnian Predil Limestone lithologic unit of the Cave del Predil was deposited in a basinal environment (Rettori *et al.*, 1998). The occurrence of *Tetrachela raiblana* in a deep-water palaeoenvironment is important in the broader context of polychelidan evolutionary history. Indeed, *T. raiblana* is one of the earliest polychelidans and several younger fossil species, for instance *Tethyseryon campanicus* Bravi, Garassino, Bartiromo, Audo, Charbonnier, Schweigert, Thévenard and Longobardi, 2014 and all species from Solnhofen-type outcrops were recorded from shallow water palaeoenvironments (Ahyong, 2009; Audo *et al.*, 2014a, 2014b, 2016). However, *T. raiblana* shows well-developed ocular incisions which suggest the presence of developed and functional eyes. This character is surprising

if we consider that *T. raiblana* lived in a deep palaeoenvironment. Indeed: (1) in modern genera, which live very deep (Galil, 2000), eyes are atrophied and non-functional (or at least almost not able to form detailed images since some species seems to react to light: Santucci, 1933); (2) *Tauricheles crymensis* (Levitski, 1974) and *Woodwardicheles neocomiensis* (Woodward, 1866), both from deep-water turbidites both have reduced ocular incisions (Audo *et al.*, in press).

Consequently, either the basinal palaeoenvironment of Cave del Predil was still shallow enough for light to be perceptible, or *T. raiblana* had developed eyes despite being in a dark palaeoenvironment. Regarding this later explanation, it is good to note that decapod crustaceans such as some species of *Glyphocrangon* Smith, 1884 were reported from depths exceeding 800 meters, and yet retain developed eyes with marked pigmentation (Komai, 2011). Similarly, species of *Metanephrops* Jenkins, 1972 are known to live in deep water, yet retain eyes and cornea pigmentation (Chan and Hu, 1991; Holthuis, 1991). For instance, the specimen MNHN-IU-2008-10509 (KARUBAR oceanographic expedition) of *Metanephrops neptunus* (Bruce, 1965) trawled at approximatively 800 m also possesses developed eyes with strong cornea pigmentation (DA pers. obs. 2018).

If *T. raiblana* migrated temporarily in Cave del Predil basinal environment, it could be behaviour related to reproduction. Indeed, extant species are known to have sex-dependant distributions, probably linked to migration of females (Santucci, 1933; Firth and Pequegnat, 1971), who have to disperse their offspring (Bernard, 1953). Unfortunately, the preservation of most specimens does not allow determining the sex of animals. In fact, one specimen preserves what resembles a petasma (poorly preserved: Fig. 2B) and could therefore be a male.

Palaeoecology

Tetrachela raiblana, as with most other fossil polychelidans, differs distinctly from extant species by its morphology, and by the environment it lived in, which was probably deep, but not as deep as that of many extant species. However, from its overall aspect, we can already deduce it was mainly benthic. Indeed, it does not seem to have any part of its anatomy streamlined enough to be a good swimmer: its carapace is stout, probably rather thick, and is covered by distinct tubercles, its pereopods are stout, and

the pleon is quite wide. Such a morphology is quite distinct from that of polychelidans which might have been nektobenthic, or at least able to swim effectively such as *Knebelia bilobata* (Münster, 1839) (which seems to possess adaptations for swimming: Audo *et al.*, 2014b) or *Willemoesiocaris ovalis* (Van Straelen, 1923) (which possesses a slender body and slender pereopods: Audo *et al.*, 2014c).

The diet of fossil polychelidans is perhaps even more complicated to study, for several reasons: (1), no direct evidence of predation has been reported so far; (2) only one specimen sufficiently well-preserved to preserve traces of its gut content is known, however, the fragments preserved in the gut are not identifiable (Jauvion *et al.*, 2016); (3) comparison with extant species is complicated because they live in very deep water, which was probably not the case for many fossil species, and because their ecology is not well-known. Nevertheless, we observe that *Tetrachela raiblana* and most other fossil species present mandible incisor process similar in shape to that of extant species. Extant species are often considered to be scavengers or predators of small invertebrates (Firth and Pequegnat, 1971; Lagardère, 1973; Gore, 1984; Cartes and Abelló, 1992). Therefore, many fossil species, as *Tetrachela raiblana*, probably had a diet similar to that of extant Polychelidae. We remark, however, that *T. raiblana*, contrary to most extant species and many fossil species, has relatively short and stocky first pereopods, similar to those of *Rosenfeldia triasica* Garassino, Teruzzi and Dalla Vecchia, 1996 (Audo *et al.*, 2017). *Tetrachela raiblana*, as *R. triasica*, was therefore unlikely to be able to catch fast moving preys by ambushing them and rapidly deploying its first pereopods, as some extant polychelidans probably do (Ahyong, 2009). *Tetrachela raiblana* was therefore more likely preying on sessile or slow-moving prey or was a scavenger.

Conclusion

Tetrachela raiblana is an important species for several reasons. First of all, to date, it is one of the oldest species of polychelidans reported. It also displays more distinctly the connections between cephalothoracic grooves, so that we were able, for the first time, to discuss the homologies between polychelidans and some other decapod carapace grooves. This new understanding of the homology of polychelidans with other decapods may prove useful for future phylogenetic work focusing on decapods.

Acknowledgements

We are grateful to our four anonymous reviewers who contributed to make our manuscript clearer and also proposed to develop further a few aspects of this research. We are pleased to thank all the museum curators who gave us access to the specimens or provided images used in this study: Christina Ifrim (Institute of Earth Science, University of Heidelberg, Germany), Irene Zorn (GBA, Wien, Austria), Alexander Lukeneder (Naturhistorisches Museum, Wien, Austria), Lucas Simonetto (MFSN, Udine, Italy), Fabio Dalla Vecchia (MPCM, Monfalcone, Italy), Claire Mellish (NHM, London, United-Kingdom), Jessica Cundiff (MCZ, Cambridge, Massachusetts, United States of America), Paula Martin-Lefèvre and Laure Corbari (MNHN, Paris). We are also pleased to acknowledge Klaus Will (Ruprecht-Karls-University Heidelberg, Germany) for preparing the picture of the lectotype of *T. raiblana*. We are grateful to four anonymous reviewers whose critical comments helped to improve the manuscript considerably. The research of MH has been supported by VEGA 02/0136/15 and Hungarian Scientific Research Fund (OTKA K112708). The extant comparative material was collected during the KARUBAR (1991; PI Kasim Moosa), MUSORSTOM 10 (1998; PI Bertrand Richer de Forges), and BOA 1 (2005; PI Sarah Samadi) research cruises - part of the Tropical Deep-Sea Benthos programme. For station data and context of the expeditions, see <https://expeditions.mnhn.fr/>.
